Abstract

We document a well-developed log-periodic power-law antibubble in China's stock market, which started in August 2001. We argue that the current stock market antibubble is sustained by a contemporary active unsustainable real-estate bubble in China. The characteristic parameters of the antibubble have exhibited remarkable stability over one year (Oct. 2002-Oct. 2003). Many tests, including predictability over different horizons and time periods, confirm the high significance of the antibubble detection. We predict that the Chinese stock market will stop its negative trend around the end of 2003 and start going up, appreciating by at least 25% in the following 6 months. Notwithstanding the immature nature of the Chinese equity market and the strong influence of government policy, we have found maybe even stronger imprints of herding than in other mature markets. This is maybe due indeed to the immaturity of the Chinese market which seems to attract short-term investors more interested in fast gains than in long-term investments, thus promoting speculative herding.

1 Introduction

After the Third Plenary Session of the 11th Central Committee of the Communist Party of China in December 1978, China adopted new reform policies and committed to open to the outside. These reforms have favored China an unprecedented growth in Gross Domestic Product (GDP). If we normalize the GDP index (deflated by the Consumer Price Index (CPI) for inflation) to 100 in 1978, then the GDP index grew to 781.2 in 2001 [1]: China’s economy has grown about 9% per year on average. In the past two decades, China has experienced a transition from a centrally planned economy to a market economy. During this period, one of the most important development has been the setup of the Chinese stock market, which has played an increasingly important role in the transition of the economy.

Before the foundation of People’s Republic of China in 1949, the Shanghai stock exchange was the third largest worldwide, after New York and London and its evolution over the period from 1919 to 1949 had enormous influence on other world-class financial markets [2]. After 1949, China implemented policies of a socialist planned economy and the government controlled entirely all investment channels. This proved to be efficient in the early stage of the economy reconstruction, especially for the heavy industry. However, planned economic policies have unavoidably led to inefficient allocation of resources. In 1981, the central government began to issue treasury bonds to raise capital to cover its financial deficit, which reopened the China’s securities markets. After that, local governments and enterprises were permitted to issue bonds. In 1984, 11 state-owned enterprises became share-holding corporations and started to provide public offering of stocks. The establishment of secondary markets for securities occurred in 1986 when over-the-counter markets were set up to trade corporation bonds and shares. The first market for government-approved securities was founded in Shanghai on November 26, 1990 and started operating on December 19 of the same year under the name of the Shanghai Stock Exchange (SHSE). Shortly after, the Shenzhen Stock Exchange (SZSE) was established on December 1, 1990 and started its operations on July 3, 1991.

Thanks to the establishment of the SHSE and SZSE, the Chinese stock market² has grown rapidly. In 1991, the total market capitalization was 284.4 billion yuan (13.2% of GDP) with the float market capitalization being 85.1 billion yuan (3.94% of GDP). In 2002, the total market capitalization was 4,033.7 billion yuan in total (39.4% of GDP) with 1,167.4 billion of float market capitalization (11.4% of GDP)³. The historical high happened in 2000 when

² By “Chinese stock market”, we refer to that in the mainland of China.

³ Since 1995, the exchange rate of *Renminbi* (RMB) yuan has been pegged to the US dollar with small fluctuations allowed around 8.27 yuan per US dollar.

the total market capitalization reached 4,968 billion yuan (55.5% of GDP) with 1,535.4 billion yuan of float market capitalization (17.2% of GDP). The size of the Chinese stock market has increased remarkably.

There are different types of China-related stock shares, including several tradable shares (state owned shares, legal person shares and employee shares) and untradable shares (A-shares, B-shares, H-shares, red chips and other foreign shares including N-shares and S-shares). A mainland Chinese company qualifying for equity issuance has to keep about 67% of its capital in the form of state-owned shares and legal person shares and can only issue up to 33% of its capital in the form of A- and/or B- and/or H-shares and/or employee shares during initial public offering (IPO) [2]. Only A-shares and B-shares are traded in the SHSE and SZSE. Despite of the separation of A- and B-shares, their daily (log) returns are correlated as a result of the information transmission mechanism at work [3]. There are many problems in the emerging Chinese stock market which include (i) small scale, (ii) instability, (iii) untradability of more than 2/3 of the shares, (iv) absence of shorting, (v) significant impact of government policies, (vi) over-speculation, (vii) over-valuation of the markets, (viii) widely taken short-term positions, (ix) insider trading, and (x) distempered regulation system [4]. These specific features make the market exhibit strong idiosyncracies and puzzles in addition to the more common behavior of mature stock markets [5]. The foreign shares has been found to behave differently from domestic shares in several respects [6]. The commonly reported day of the week effects [7,8] are found to be absent in both Shanghai and Shenzhen A and B markets [9]. The acceptance or rejection of the random-walk hypothesis in the Chinese stock markets is controversial, and the conclusion depends on the approach used to perform the tests [10,11,2]. The markets also have extremely high volatility [2] and very high P/E (price-over-earning) ratios [12,13]. The high P/E ratios can be partially explained by the relative scarcity of shares resulting from the holding of more than 2/3 of their total number by the government.

While, as we briefly summarized, there are many problems that can distort the analysis of the Chinese stock markets, it is an interesting question to consider the possibility for behaviors similar to those which have been documented for other developed markets [14,15], in particular in view of the documented speculative nature of Chinese investors [4]. We refer in particular to the US and worldwide “antibubble” regime found to have developed after the collapse of the so-called information and internet bubble in 2000 [16,17]. We find several puzzles in the behavior of the Chinese stock markets in the last few years. The Chinese stock markets turned into a bearish antibubble regime (significantly decreasing prices) ⁴ in asynchrony with most of the major world markets

⁴ Since we have documented in the past two types of antibubbles, one bullish and the other bearish [17,18,19,20], we refer to the bearish antibubble type when we use

[17] and significantly later at a time when China's economy was still doing well. The SHSE Composite Index culminated at the all-time high of 2242.4 on 2001/06/13 and since plummeted 32.2% to 1520.7 on 2001/10/22. It reached its minimum at 1319.9 on 2003/01/03, with many strong preceding local ups and downs. Notwithstanding the asynchrony with the rest of the world, we will show below that the evolution of the Chinese stock markets since mid-2001 can be quite well described by the same concept of an antibubble.

The paper is organized as follows. In Sec. 2, we describe the data sets. In Sec. 3, we identify separately two signatures of an antibubble characterizing the trajectory of the SHSE Composite Index: (i) a power-law relaxation and (ii) log-periodic undulations. A combined log-periodic power-law (LPPL) analysis in Sec. 4 further confirms the existence of an antibubble in the Chinese stock market. We investigate the statistical properties of the fit residuals in We test in Sec. 5 the predictive potential of our characterization of an antibubble regime. Section 6 compares the 2001 China antibubble with other documented antibubbles and describe how the antibubble was gestated and how it developed. Finally, Sec. 7 concludes.

2 Data sets

There are many different indexes published by SHSE, SZSE and other investment companies. These indexes can be decomposed into four categories: composite indexes, sample share indexes, classified indexes and other indexes. We have retrieved fourteen indexes produced by three organizations, that is, the SHSE, the SZSE and TX Investment Co. Ltd. whose indexes are also well-known and widely adopted by investors⁵. These indexes are the SHSE Composite Index (SHSE_CI), SHSE 180 Index (SHSE_180), SHSE A Share Index (SHSE_A), SHSE B Share Index (SHSE_B), SZSE Composite Index (SZSE_CI), SZSE A Share Subindex (SZSE_SA), SZSE B Share Subindex (SZSE_SB), TX 280 Index (TX_280), TX Total Share Index (TXT), TX SHSE Total A Share Index (TXT_SH_A), TX SZSE Total A Share Index (TXT_SZ_A), TX Float Share Index (TXF), TX SHSE Float A Share Index (TXF_SH_A), and TX SZSE Float A Share Index (TXF_SZ_A).

The SHSE and SZSE indexes are from 2000/08/09 to 2003/10/28 and the TX indexes are from 2000/08/09 to 2003/10/22. The normalized times series of these indexes to zero mean and unit variance are drawn in Fig. 1. One can see that, apart from the two B-share-related indexes SHSE_B and SZSE_SB which exhibit significant deviations, the other twelve indexes show quite similar tra-

the term “antibubble” in this paper as it is the only relevant in the present study.

⁵ See <http://www.txsec.com>

Fig. 1. (Color online) Comparison of 14 normalized indexes: SHSE Composite Index (SHSE_CI), SHSE 180 Index (SHSE_180), SHSE A Share Index (SHSE_A), SHSE B Share Index (SHSE_B), SZSE Composite Index (SZSE_CI), SZSE A Share Subindex (SZSE_SA), SZSE B Share Subindex (SZSE_SB), TX 280 Index (TX_280), TX Total Share Index (TXT), TX SHSE Total A Share Index (TXT_SH_A), TX SZSE Total A Share Index (TXT_SZ_A), TX Float Share Index (TXF), TX SHSE Float A Share Index (TXF_SH_A), and TX SZSE Float A Share Index (TXF_SZ_A).

jectories with relatively minor differences. In this paper, we shall present our results based on the SHSE Composite Index but all our conclusions remain valid for other eleven indexes with similar behavior.

3 Power law and log-periodicity

The assumption that there is a critical point at the inception of an antibubble can be tested by investigating market behavior close to criticality. Two possible signatures of a singular or critical behavior might appear during the development of an antibubble: a power law relaxation and log-periodic wobbles. In this section, we analyze these two features separately. A combined log-periodic power-law analysis is presented later in Sec. 4.

3.1 Power law relaxation

The power law expression for an antibubble reads

$$I(t) = A + B(t - t_c)^m, \quad (1)$$

where t_c is an estimate of the inception of the antibubble, $t > t_c$, and the order parameter $I(t)$ can be the price $p(t)$ or its logarithm $\ln[p(t)]$. We shall discuss which of these two choices is the more pertinent for $I(t)$ in the next section. If $m < 0$, $I(t)$ is singular when $t \rightarrow t_c^+$ and B should be found positive to ensure

that $I(t)$ decreases. If $0 < m < 1$, $I(t)$ is finite but its first derivative $I'(t)$ is singular at t_c and B should be found negative to ensure that $I(t)$ decreases.

We fit the SHSE Composite Index from 2001/08/09 to 2003/10/10 using the power law formula (1). The fit with $I(t) = \ln[p(t)]$ is illustrated in Fig. 2 as a solid line, whose parameters are $t_c = 2001/08/18$, $m = 0.15$, $A = 7.76$, and $B = -0.1691$ with a r.m.s. of the fit residuals $\chi = 0.0519$. The dashed line in Fig. 2 gives the fit for $I(t) = p(t)$, whose parameters are $t_c = 2001/08/18$, $m = 0.10$, $A = 2526$, and $B = -531.7$ with a r.m.s. of the fit residuals $\chi = 80.2$. The two fits estimate a same inception date of the antibubble and gives close power law exponents. The two fits are too close to be distinguishable in Fig. 2.

Fig. 2. Daily trajectory of the SHSE Composite Index from 2001/08/09 to 2003/10/10 (wiggly line) and fits using a power law formula (1). The continuous line is the fit to the logarithms of the SHSE Composite Index (*i.e.*, $I(t) = \ln[p(t)]$), while the dashed lines show fits to the SHSE Composite Index (*i.e.*, $I(t) = p(t)$).

3.2 Log-periodicity

The detection of log-periodic oscillations, in any, is conveniently performed by removing the global trend of the index. One way is to subtract the power law fit (1) from the index and by analyzing the wobbles of the obtained residue $s(t)$ by an adequate spectral analysis. We shall also use a non-parametric approach called the (H, q) analysis. These two methods provide a residue $s(t)$ and we stress that their results are independent of a priori assumptions of the presence of log-periodicity, a welcome property in view of some criticisms concerning a previous implementation [25] of such analysis [24].

Since log-periodicity corresponds to regular oscillations in the variable $\ln(t - t_c)$, we use a Lomb periodogram analysis which is well-adapted to the uneven sampling of the variable $\ln(t - t_c)$ [21]. A Lomb analysis also allows us to assess the statistical significance level of the extracted log-periodicity [21,22,23].

3.2.1 Parametric detrending approach

Following [25,26], the first method consists of removing the power law trend measured in Sec. 3.1. We construct the residue $s(t)$ in the following way

$$s(t) = [I(t) - A]/(t - t_c)^m, \quad (2)$$

where A , m and t_c are obtained for the fit of the pure power law formula (1) to the data, as shown in Sec. 3.1. This residue $s(t)$ has a nonzero mean μ_s and the variance σ_s^2 different from 1. The inset of Fig. 3 plots $[s(t) - \mu_s]/\sigma_s$ as a function of $\ln \tau$, where we denote

$$\tau = t - t_c. \quad (3)$$

The Lomb periodogram of this centered normalized residue considered as a function of the variable $\ln \tau$ is shown in Fig. 3. Again, the two choices $I(t) = \ln[p(t)]$ and $I(t) = p(t)$ are undistinguishable. Since $P_N(\omega)$ is a normalized Lomb power, $s(t)$ and $[s(t) - \mu_s]/\sigma_s$ have identical Lomb periodogram.

Fig. 3. Lomb periodogram analysis of $s(t)$ where $s(t)$ is considered to be a function of $\ln \tau$ where $\tau = t - t_c$. In other words, ω is the log-angular frequency conjugate to $\ln \tau$; thus a strong significant peak of the periodogram qualifies the existence of log-periodicity. The two choices $I(t) = \ln[p(t)]$ and $I(t) = p(t)$ have been considered and give the same undistinguishable results. The inset shows the centered normalized residue $[s(t) - \mu_s]/\sigma_s$ as a function of $\ln \tau$. Note that $P_N(\omega) < 10$ for $\omega > 50$ so that the part of the spectrum shown here exhibits the most relevant part.

The highest peak for $I(t) = \ln[p(t)]$ ($I(t) = p(t)$) is at $\omega = 11.29$ (11.31) with height $P_N = 93.3$ (92.7). This gives a false alarm probability⁶ $\Pr \ll 10^{-5}$ (10^{-5}) for white noise [21]. If the residues have long range-correlations characterized by a Hurst index $H > 1/2$, we have $\Pr < 10^{-5}$ for $H = 0.6$, $\Pr = 0.001$ for $H = 0.7$, $\Pr = 0.02$ for $H = 0.8$, and $\Pr = 0.10$ for $H = 0.9$. The second highest peak is at $\omega = 5.82$ (5.74) with $P_N = 50.8$ (51.2). We

⁶ False alarm probability is the chance that we falsely detect log-periodicity in a signal without true log-periodicity.

interpret these two highest peaks as a fundamental log-periodic component at $\omega_f = 5.82$ (5.74) and its harmonic component at $2\omega_f$.

3.2.2 (H, q) -analysis

We have also performed a generalized q -analysis, called (H, q) -analysis, on $I(t)$, which is a non-parametric method for characterizing self-similar functions. The (H, q) -analysis [27,28] is a generalization of the q -analysis [29,30], which is a natural tool for the description of discretely scale invariant fractals. The (H, q) -derivative is defined as

$$D_q^H I(\tau) \triangleq \frac{I(\tau) - I(q\tau)}{[(1-q)\tau]^H}. \quad (4)$$

The special case $H = 1$ recovers the standard q -derivative, which itself reduces to the standard derivative in the limit $q \rightarrow 1^-$. There is no loss of generality by constraining q in the open interval $(0, 1)$ [27]. The advantage of the (H, q) -analysis is that there is no need for detrending, as it is automatically accounted for by the finite difference and the normalization by the denominator.

We apply the (H, q) -analysis to $I(x) = \ln p(t)$ to check for the existence of log-periodicity. The results obtained for $I(t) = p(t)$ are very similar. The independent variable is taken to be $\ln \tau$, with t_c equal to the value $t_c = 2001/08/18$ estimated above from the simple power law fit (1) [27]. The same method has been applied to test for log-periodicity in stock market bubbles and antibubbles [16,28], in the USA foreign capital inflow bubble ending in early 2001 [43], and in the ongoing UK real estate bubble [42].

For each pair of (H, q) values, we calculate the (H, q) -derivative, on which we perform a Lomb analysis. We find that most of the Lomb periodograms have a shape similar to that shown in Fig. 3. The highest Lomb peak of the resultant periodogram has height P_N and abscissa ω with height, both P_N and ω being functions of H and q . We scan a grid of 100×50 rectangular in the (H, q) plane, with $H = -0.99 : 0.02 : 0.99$ and $q = 0.01 : 0.02 : 0.99$. Figure 4 shows the bivariate distribution of pairs (ω, P_N) . The inset gives the marginal distribution of ω 's in the interval $0 < \omega < 15$. The two most prominent clusters correspond respectively to $\omega_f = 5.42 \pm 0.34$, identified as the fundamental angular log-frequency and to $2\omega_f = 11.50 \pm 0.38$ interpreted as its harmonics. We also find a total of five pairs with $\omega > 13$. All these five pairs have the same $\omega = 21.42$, which is very close to $4\omega_f$. This suggests that the first, second and fourth harmonics are expressed in the signal. However, the fourth harmonic has a weak spectral amplitude $P_N = 5.5 \sim 5.6$. Other smaller clusters are most probably due to noise decorating the power law [31] or due to a residual global trend in the (H, q) -derivative. In summary, this (H, q) -analysis provides even stronger evidence for the existence of log-

periodicity than the parametric detrending approach of the previous section 3.2.1.

Fig. 4. Bivariate distribution of pairs (ω, P_N) defined as the highest Lomb peaks of the (H, q) -derivative of $I(t) = \ln[p(t)]$. Each point in the figure corresponds the highest Lomb peak and its associated angular log-frequency in the Lomb periodogram of the (H, q) -derivative of $I(t) = \ln[p(t)]$ for a given pair (H, q) . The inset shows the marginal distribution of ω in the interval $0 < \omega, 13$.

4 A combined log-periodic power law analysis of the 2001 Chinese antibubble

We have shown that, since August 2001, the SHSE Composite Index qualifies as a critical antibubble according to two signatures of a power law relaxation (no strong discriminant) decorated by log-periodic oscillations (very discriminant). In this section, we perform a combined parametric analysis of these two signatures, using a log-periodic power law (LPPL) formulation.

4.1 Fit with first-order LPPL formula

This LPPL formulation is based on the following principles. Investors in the stock market form a small-world network [32,33] and interact with each other “locally” by imitation. Local interactions propagate spontaneously into global cooperation leading to herding behaviors, which result in bubbles and antibubbles. These ingredients together with an assumption that prices reflect the imitative properties of the system can be captured by rational imitation models of bubbles and antibubbles [25,26,34]. The main consequence of the model is that the dynamics may evolve towards or away from a critical point or critical time t_c corresponding to the most probable end of the bubble or beginning of the antibubble. The competition between nonlinear trend followers and nonlinear value investors together with inertia between investor

decisions and their market impact may lead to additional nonlinear oscillations approximating a log-periodicity [35,36]. Log-periodicity may also result or be amplified by the existence of a naturally existing hierarchy of social group sizes [26,34,37].

Mathematically, the LPPL structure can be expressed as:

$$I(t) = A + B\tau^\alpha + C\tau^\alpha \cos[\omega \ln(\tau) - \phi], \quad (5)$$

where ϕ contains two ingredients: the information on the mechanism of interactions between investors and a rescaling of time [18,19]. The distance to the critical time is $\tau = t_c - t$ for bubbles and $\tau = t - t_c$ for antibubbles.

Theoretically, the order parameter $I(t)$ can be the price $p(t)$ or the log of price $\ln[p(t)]$, depending on the following criterion. Let us assume that the observed price is the sum $p(t) = F(t) + M(t)$ of a fundamental price $F(t)$ and of a bubble or an antibubble $M(t)$. We have $I(t) = p(t)$ when $F \ll M$ and $I(t) = \ln[p(t)]$ when $F \sim M$ [38,34]. The difficulty is that only $p(t)$ is observed and one does not know how to decompose it into a fundamental contribution and a bubble or antibubble component. A statistical test using the distributions of the ω and m can be used to determine the relevant order parameter [34] but is not always discriminant. For the lack of a better argument, we try both possibilities and we fit the Shanghai Stock Exchange Composite index from 2001/08/09 to 2003/10/10 using (5) with either $I(t) = p(t)$ or $I(t) = \ln[p(t)]$. It turns out that the two cases give results that are undistinguishable, as in the above analyses. We follow the numerical algorithm described in Ref. [16].

Figure 5 shows the fit of the SHSE Composite Index (wiggly line) by the LPPL formula (5) (continuous line) using $I(t) = \ln[p(t)]$. The fit parameters are $t_c = 2001/08/12$, $m = 0.28$, $\omega = 11.45$, $\phi = 1.77$, $A = 7.62$, $B = -0.0517$, $C = -0.0097$, and the r.m.s. of the fit residuals is $\chi = 0.0385$. We have used calendar days as unit of time. At least five LPPL oscillations are clearly visible in the figure.

Using $I(t) = p(t)$, we find the following parameters $t_c = 2001/08/12$, $m = 0.23$, $\omega = 11.35$, $\phi = 1.14$, $A = 2084$, $B = -138.3$, $C = -20.5$, and the r.m.s. of the fit residuals is $\chi = 60.6$, corresponding to the dashed line shown in Fig. 5. The two fits produce almost the same trajectory and basically the same extrapolation. Both fits give very close values for t_c , ω and m . In the rest of this paper, we shall thus mostly use $I(t) = \ln[p(t)]$, as there is no need to duplicate almost identical results with $I(t) = p(t)$.

Fig. 5. Daily trajectory of the SHSE Composite Index from 2001/08/09 to 2003/10/10 (wiggly line) and fit using the LPPL formula (5). The continuous line is the fit to the logarithms of SHSE Composite Index (*i.e.*, $I(t) = \ln[p(t)]$), while the dashed line shows the fit to the SHSE Composite Index (*i.e.*, $I(t) = p(t)$). Both fits are almost undistinguishable.

4.2 Fit with second-order Weierstrass-type function

While the LPPL formula (5) is able to synchronize with the major oscillations of the Shanghai Stock Exchange Composite index, there are significant discrepancies in amplitudes. This should not be too surprising as expression (5) is just the first term in a systematic Fourier series of harmonics. The Lomb periodograms discussed above have shown the importance of second and higher-order harmonics. Actually, the existence of a systematic series of log-periodic terms is expected on general grounds from the mathematical formulation of discrete scale invariance in terms of a discrete renormalization group map R such that $\tau' = R(\tau)$ and $\mathcal{F}(\tau) = \mathcal{G}(\tau) + \frac{1}{\mu}\mathcal{F}[R(\tau)]$ [39], where $\mathcal{F}(\tau) = \ln[p(t)] - \ln[p(t_c)]$ such that $\mathcal{F} = 0$ at the critical point at t_c , $\tau = |t - t_c|$ is the distance to the critical point occurring at t_c , and $\mu > 1$ describes the scaling of the index evolution upon a rescaling of time. These equations can be solved in the form of an infinite series which can be re-summed by applying the Mellin transform to exhibit the singular part [40]. This formalism suggests therefore to add at least a second harmonic to (5). More terms can be taken into account to describe Weierstrass-type functions as in Refs.[40,41,42]. The corresponding expression generalizing formula (5) reads

$$I(t) = A + B\tau^m + \Re\left(\sum_{n=1}^N C_n e^{i\psi_n} \tau^{-s_n}\right). \quad (6)$$

This formula (6) with $N = 2$ proved to outperform our former specification in terms of a first-order LPPL function (5) for the modelling of the worldwide 2000-2002 anti-bubbles that started in mid-2000 [16,17,20] and of the 1975-2001 bubble in the American foreign assets capital inflow [43].

Fitting the SHSE Composite Index from 2001/08/09 to 2003/10/10 for $I(t) = \ln[p(t)]$ with expression (6) with $N = 2$ gives the following parameter values: $t_c = 2001/08/06$, $m = 0.12$, $\omega = 5.83$, $\phi_1 = 2.33$, $\phi_2 = 6.20$, $A = 7.89$, $B = -0.2692$, $C = 0.0180$, $D = 0.0253$, and the r.m.s. of the fit residuals is $\chi = 0.0319$. For $I(t) = p(t)$, we get $t_c = 2001/08/03$, $m = 0.06$, $\omega = 6.09$, $\phi_1 = 3.84$, $\phi_2 = 0.00$, $A = 3300$, $B = -1233.3$, $C = 41.8$, $D = -53.2$, and the r.m.s. of the fit residuals is $\chi = 50.0$. It is worth noting that the fact that $|C| < |D|$ implying a stronger second harmonic component is consistent with the result in Fig. 3 showing a higher peak at $2\omega_f$. Note that the inclusion of the second harmonic is able to account well for the major features of the SHSE Composite Index trajectory, while higher frequency effects, such as jumps and crashes, are still poorly described and would require higher order terms.

Fig. 6. Daily trajectory of the SHSE Composite Index from 2001/08/09 to 2003/10/10 (wiggly line) and fits using a second-order Weierstrass-type LPPL formula (6). The continuous line is the fit to the logarithms of the SHSE Composite Index (*i.e.*, $I(t) = \ln[p(t)]$), while the dashed line shows the fit to the SHSE Composite Index (*i.e.*, $I(t) = p(t)$).

As shown in Fig. 6, the two fits are very close with consistent future scenarios. A comparison of the first- and second-order fits shows that they are remarkably consistent in the sense that both fits give close estimates of the critical time t_c , a small power law exponent m , and the same fundamental angular log-frequency $\omega \approx 6$. The existence of a fundamental angular log-frequency and its high-order harmonics is a strong signal of the significance of the log-periodicity. We shall elaborate further on this point later.

4.3 Fit with second-order Landau expansion function

Another extension to the log-periodic function (5) is to allow for nonlinear coupling between harmonics, by rewriting the fundamental existence of a critical

exponent in terms of the following Landau expansion [44]:

$$\frac{dI(\tau)}{d \ln \tau} = \alpha I(\tau) + \beta |I(\tau)|^2 I(\tau) \dots, \quad (7)$$

where the coefficients may be generally complex. Starting with the Landau expansion in the vicinity of the critical point $\tau = 0$, the first order term recovers Eq. (5), while the second order gives:

$$I(t) = A + \frac{B\tau^m + C\tau^m \cos \left[\omega \ln(\tau) + \frac{\Delta_\omega}{2m} \ln \left(1 + \left(\frac{\tau}{\Delta_t} \right)^{2m} \right) + \phi \right]}{\sqrt{1 + \left(\frac{\tau}{\Delta_t} \right)^{2m}}}. \quad (8)$$

Higher orders in the Landau expansion add additional degrees of freedom and allow a more precise description [45], however at the cost of more numerous parameters to fit. The value of a given order should always be determined by the tradeoff between a better fit and the parameter cost.

Expression (8) has an approximate power law envelop and describes a transition from a log-periodicity with angular log-frequency ω for $\tau < \Delta_t$ to a log-periodicity with angular log-frequency $\omega + \Delta_\omega$ for $\Delta_t < \tau$. For instance, the 1990 Nikkei antibubble experienced the transition from the first-order Landau description (5) to the second-order Landau formula (8) 2.5 years after the inception of the antibubble [45,46]. In contrast, the 2000 S&P 500 antibubble has just entered the second-order Landau regime, on the fourth quarter of 2003 after three years [16,47]. Using the LPPL Landau expansion up to the third order, a prediction was published in January 1999 on the behavior of the Japanese stock market in the following two years [45], which has been remarkably successful [46].

We fit the SHSE Composite Index to the second-order Landau formula (8) as shown in Fig. 7. The fit parameters for $I(t) = \ln[p(t)]$ are $t_c = 2001/08/12$, $\alpha = 0.37$, $\omega = 6.36$, $\phi = 1.09$, $\Delta_t = 3807$, $\Delta_\omega = -93.3$, $A = 7.62$, $B = -0.0323$, $C = 0.0066$, and the r.m.s. of the fit residuals is $\chi = 0.0363$. The fit parameters for $I(t) = p(t)$ are $t_c = 2001/08/15$, $\alpha = 0.36$, $\omega = 5.89$, $\phi = 0.21$, $\Delta_t = 4757$, $\Delta_\omega = -99.9$, $A = 1990$, $B = -54.3$, $C = -10.8$, and the r.m.s. of the fit residuals is $\chi = 56.7$.

In contrast with the fits with (5) or (6), expression (8) smoothes out the oscillations and other fluctuations at early times of the antibubble but captures adequately the later oscillations with correct amplitude. This phenomenon was also observed in the Nikkei case where the oscillations in the first two months disappeared when using (8) [45], suggesting that they lack significance. As Δ_t is more than ten years, this would lead to conclude that the transition expected for the angular log-frequency to the second order regime has not yet started. However, this conclusion is not completely warranted in the present case in

Fig. 7. Daily trajectory of the SHSE Composite Index from 2001/08/09 to 2003/10/10 (wiggly line) and fits using a second-order Landau expansion LPPL formula (8). The continuous line is the fit to the logarithm of the SHSE Composite Index (*i.e.*, $I(t) = \ln[p(t)]$). The dashed lines show the fit to the SHSE Composite Index (*i.e.*, $I(t) = p(t)$).

view of the large values found for Δw , which implies a more complex crossover from the second-order Landau expansion to the first order as Δ_t increases.

5 Predictive power of LPPL formulae

5.1 When was the antibubble detectable?

As we have shown that the Chinese stock markets antibubble started in August 2001, an interesting question arises naturally: how long after its inception would we have been able to detect the antibubble? This question amounts to testing the stability of the antibubble.

In this goal, we fit the SHSE composite index from 2001/08/09 to different ending date t_{last} with the first-order LPPL formula (5). Thirty ending dates t_{last} have been used, taken equidistant in the time interval from 2002/01/10 to 2003/10/28. This gives 30 fits and thus 30 groups of parameters. Fig. 8 shows the three most important parameters ω , m and t_c as functions of t_{last} .

Panel (a) of Fig. 8 shows that the angular log-frequency are stable after $t_{\text{last}} = 2003/03/04$ with $\omega = 11.29 \pm 0.25$, as ten ω 's are in the interval (11, 12) and one in the interval (10, 11). In the time interval from 2002/11/14 to 2003/03/04, we find $\omega = 5.15 \pm 0.13$, which is half the value for later t_{last} . It thus seems apparent that the fit has oscillated between locking in on the fundamental or on its harmonic. The values of m and t_c are also remarkably stable after 2002/11/14. We find $m = 0.24 \pm 0.04$ and $t_c = 2001/08/14 \pm 4$ (calendar

Fig. 8. Fitted parameters as functions of the end t_{last} of the fitted interval since the inception of the Chinese antibubble: (a) ω , (b) m , and (c) t_c .

days) for t_{last} after 2002/11/14. If we use the following three criteria for the qualification of the antibubble: (1) its angular log-frequency ω should close to ω_f or its harmonics, (2) its exponent m should be less than 0.5 (to describe a significant power law decay), and (3) its estimated critical time t_c should be in August of 2001, then we conclude that the antibubble could have been detected from the end of 2002. We note that these three criteria are also met for $t_{\text{last}} = 2002/07/27$ and $t_{\text{last}} = 2001/08/12$, two dates which could have provided early precursors. These criteria are similar to those used in advance predictions of crashes (see [48,14]).

Thus, should we have detected the Chinese antibubble as early as 2002/07/27 before we started our own work in September 2002 on the worldwide antibubble that started in August 2000? The answer is probably negative because such early detection would not have been confirmed by the stability of the fitted parameters. This example stresses the importance of verifying the stability of parameters over successive time periods, before concluding about the detection of a LPPL bubble or antibubble. The 2002/07/27 alarm occurred as an isolated case and could have been by chance. We can however state with confidence that the existence of the antibubble could have been confirmed by the end of 2002, based on the series of confirmation of the three criteria from November 2002. After 2003/03/04 when the fitted ω is found close to $2\omega_f$, the confirmation of the existence of the antibubble is even stronger because the occurrence of precisely defined harmonics is a strong telling presence of a non-random signal.

5.2 Predictability of market direction and optimal horizon

An even better test for qualifying the Chinese LPPL antibubble is to check if anomalous predictions can be obtained. We assess the predictive power of

the LPPL framework in the following way. We define a fixed horizon Δt and perform LPPL fits with expression (5) to the SHSE composite index (using $I(t) = \ln[p(t)]$) from 2001/08/09 to a given time t . We then extrapolate the fit from t to $t + \Delta t$ using the fit and thus obtain a prediction for the sign of the expected return $r(t, \Delta t) = I(t + \Delta t) - I(t)$ over the next time period Δt . We then perform the same operations for the SHSE composite index up to the time $t + \Delta t$, and so on in time steps of Δt until the end date of 2003/10/28 is reached. We are thus able to construct the percentage of times when the fit predicts the correct market direction. We do this for different starting times of the procedure, called t_{enter} (corresponding to a fictitious situation of a trader starting to apply our strategy from t_{enter} till 2003/10/28). We have used six different t_{enter} : 2002/01/04, 2002/04/12, 2002/07/12, 2002/10/14, 2003/01/07, and 2003/04/10. We also perform the analysis of different time horizon Δt from 1 day to 100 days. This gives us a bivariate percentage function $P(t_{\text{enter}}, \Delta t)$ of success, which is shown in Fig. 9.

Fig. 9. Percentage $P(t_{\text{enter}}, \Delta t)$ of successful predictions of the market direction for six different beginning times t_{enter} for the application of our strategy (explained in the text) and for various time horizons.

For fixed time horizon Δt , the success percentage $P(t_{\text{enter}}, \Delta t)$ increases with t_{enter} , reflecting the increasing reliability of the fit with the maturation of the antibubble. For fixed entering date t_{enter} , $P(t_{\text{enter}}, \Delta t)$ has a clear maximum at about 30 trading days (about six calendar weeks), except for the most recent one for which $P(t_{\text{enter}}, \Delta t)$ increases monotonically with Δt . This optimal Δt for the first five t_{enter} results from the competition between noise (high-frequency price changes), which favors a larger Δt , and the need to finely tune the fit to recent data, which favors a smaller Δt . We note that the high predictability found using our methodology does not translate in gains when negative returns are predicted because shorting is forbidden in the Chinese stock markets. The best that can be done is to exit the market and keep one's wealth in a risk-free investment.

These findings have similarities and differences with those obtained for the US market for a similar time period (see Fig. 7 of [41]). In the case of the

US S&P 500 index, $P(t_{\text{enter}}, \Delta t)$ is an approximately increasing function of Δt and remains unchanged for different t_{enter} . However, it is interesting that $P(t_{\text{enter}}, \Delta t)$ for the US markets also exhibits a locally maximum for $\Delta t \approx 30$ days as for the Chinese stock market, suggesting that the quality of the LPPL signal for prediction compared with the amount of noise are similar. We also find a larger predictability (larger $P(t_{\text{enter}}, \Delta t)$) for not too large Δt in the Chinese compared with the US stock markets.

5.3 What scenario for the future of the Chinese stock markets?

The cumulative evidence provided by our tests presented above suggests to use our detection of an antibubble regime to predict the future evolution of the Chinese stock market, similarly to the advanced prediction in January 1999 for the Japanese Nikkei index [45,46] and the advance prediction in December 2002 for the US S&P500 index [16].

In order to get the most robust and reliable advanced prediction, we use the three different implementation of our LPPL theory described above (first-order LPPL formula (5), LPPL with the second harmonic (6) and second-order Landau expansion formula (8)). The advanced predictions are obtained by simply extrapolating the fits with these three formulas performed using the data up to 2003/10/28. The results shown in Fig. 10 predict that the negative trend will bottom at the end of the year 2003. The first-order LPPL formula and the second-order Weierstrass-type formula predict that the rebound will end six or seven months later, while the second-order Landau formula is more pessimistic in the sense that it predicts an earlier termination of the coming bull market. In addition, the Landau formula (8) forecast a slightly earlier recovery time.

Fig. 10. (Color online) Forward prediction of the Chinese stock market obtained by extrapolating the fits of the SHSE composite data until 2003/10/28 using three different formulae explained in the legend.

However, there are two subtle issues we have to keep in mind. First of all, our attempt to predict by extrapolating to the future does not mean that we think the bearish market will continue forever. Due to the large value of Δ_t (see Sec. 4.3) and the rather stable parameters values (see Sec. 5.1), the current antibubble has not entered a phase shifting process and it is too early to detect such phase shift [47]. In addition, since the Chinese stock markets are rather immature and heavily affected by government policies [4], the current antibubble may terminate at some time in the future suddenly due to some unexpected exogenous shock.

Let us add a cautionary note with respect to the predicted amplitudes. As we can see in Fig. 10, the dips are not well captured by the fits which are by construction “low frequency.” Specifically, the two dips in January of 2002 and of 2003 were much deeper and more severe than described by the fits. A similar dip could occur also close to the predicted minimum corresponding to a plunge of the SHSE composite index below 1300 sometimes in the remaining months of the year 2003.

6 Universality versus idiosyncrasy of the China antibubble

6.1 Comparison with other antibubbles

The recognition of the present regime of the Chinese stock market as an antibubble is tantamount to an attempt to classify universal regimes in the dynamics of stock markets. It is thus important to compare the 2001 Chinese stock market antibubble with those in the other stock markets.

Several periods after 1990 have been classified as stock market antibubbles:

- (1) the Japanese Nikkei 225 antibubble started in January 1990 which lasted over ten years [45];
- (2) the Argentina antibubble started in June 1992 which lasted about six months [34];
- (3) the January 1994 antibubbles in Australia, France, Hong Kong, Italy, New Zealand, Spain, Switzerland, and the United Kingdom which lasted half to one year [34];
- (4) the Chile antibubble which started in July 1995 and lasted about nine months [34];
- (5) the September 1997 antibubbles in Russia [25] and Venezuela [34] which lasted about ten months;
- (6) the worldwide August 2000 antibubble in 23 indexes worldwide which has apparently not ended yet [16,17,20].

Among all these cases, two in 1994 and 2000 involve several or many countries simultaneously, suggesting the existence of strong coupling and contagion mechanisms. All the others appear to be localized to single markets. In the global 1994 antibubble, the coupling was apparently delocalized across the different markets with not clear single directing factor. In the case of the 2000 antibubble, it seems that the US market was and remains the leading factor affecting the other markets, as witnessed by the extraordinary synchronization of other markets with the US market (see figure 31 in [17]).

The current 2001 Chinese stock market antibubble occurs at a time of a world-wide antibubble but remains by and large decoupled from it. It seems that the Chinese antibubble is an example in which idiosyncratic mechanism dominate over global coupling and contagion. Let us compare further the 2001 China antibubble and the 2000 global antibubble. We have previously investigated the inter-dependence between the SHSE Composite Index and the US S&P500 Index including data up to December 2002, using several measures of inter-dependence [17]: the cross-correlation of weekly returns, linear regressions of indices and of their returns [52], a synchronization ratio of joint occurrences of ups and downs [17] and an event synchronization method recently introduced [53]. The China stock market was found to be uncorrelated or slightly anti-correlated with the US market with a cross-correlation coefficient of synchronous weekly returns of about -0.06 in a three-month moving window. This should be compared with the west European markets (France, Germany, Netherland, UK, *et al.*) which have a cross-correlation coefficient of about 0.3 with the US market [17]. Comparing the Chinese antibubble since August 2001 directly with the western antibubbles since August 2000, we find that the daily return cross-correlation is very low (-0.020 with the US S&P 500 index, 0.008 with the leading German index and -0.037 with the leading French index, to list a few), while the return cross-correlation coefficients between the western antibubbles are significantly higher (0.665 between US and Germany, 0.539 between US and France and 0.847 between Germany and France). In a nutshell, the Chinese stock market has almost no correlation with the major western stock markets despite their increasing mutual international trading.

From the view point offered by the LPPL formulas, the weak or non-existent correlation between the Chinese antibubble and the antibubbles of western markets can be attributed to the conjunction of (1) different inception times t_c , (2) different angular log-frequencies (and especially the existence of two angular log-frequencies with similar amplitudes in the Chinese case) and (3) different exponents ($\frac{1}{2} < m < \frac{3}{2}$ for most of the western markets compared with $0 < m < \frac{1}{2}$ for China).

6.2 *Particularities of the Chinese stock market*

The fundamental reason underlying the special behavior of the Chinese stock market compared with western markets lies in its immaturity and the strong influence of the government which still keeps a strong control.

In developed countries, profits and dividends are the cornerstones of a fundamentally strong and mature stock market [54]. The performance of a stock is strongly correlated with the output of the company. Putting money into these market is an investment more than a speculative gambling (except during the late stage of speculative bubbles [55,56,?,57,14]). In contrast, in the Chinese stock markets, activities are far from regularized. Many companies attempt to collect money by issuing equities, while the interest of the investors is not under careful consideration. Some of the companies report inflated data of output in order to issue new stocks and snatch more money (this is not completely different from recent reported mispractice in the US and elsewhere). This practice is particularly evident in the extremely high initial public offerings (not unlike the extreme IPOs of the late stage of the 2000 information and technology bubble in the US). Therefore, the Chinese stock market is more of a speculation market than an investment market [4]. One could observe that the stock prices soared during the bubble from May 1999 to June 2001 while the confidence of investors decreases. The 1999-2001 bubble was thus even more unsustainable than standard bubbles, and its inherent instability eventually leads to a strong correction [14,15].

Institutional investors provide a significant fraction of the capital invested the Western financial markets. In the US as of November 2003, more than half of US households are invested in mutual funds which hold \$7 trillion in assets, almost half the total US market capitalization. Notwithstanding recent scandals, mutual funds are supposed to be more rational and to invest on longer term than speculative agents, with positive stabilizing effects. In contrast, a widely-accepted view is that the Chinese stock markets are dominated by individual investors who are driven by short term benefit making the markets highly volatile [4,58]. However, there are some dissonant views arguing that the proportion of individual investors is exaggerated and institutional investors including formal funds (a proportion of 5% of the tradable market capitalization by April 2001) and privately raised funds (a proportion of 43% of the tradable market capitalization by April 2001) occupy a large part in the Chinese stock markets [59,60]. It is also argued that privately raised funds have tighter ties with individual investors [59]. In general, the Chinese stock markets respond to exogenous information, such as firm's accounting information, stock exchanges announcement, government policies, and so on [61,62,63].

During the development of the "May 1999 - June 2001" bubble, several uncer-

Fig. 11. Attempt to fit the (logarithm of the) SHSE Composite Index from January 1999 to July 2001, using expression (5) with $\tau = |t_c - t|$, in order to test whether we can detect a speculative bubble preceding the crash in July 2001.

tainties coexisted that made investors rather sensitive to government policies. The largest uncertainty was related to the untradable shares. It has long been realized by investors and by the Chinese government that the huge proportion of the untradable shares blocks the healthy development of the Chinese stock markets [4]. The problem is how and when to reduce the holding of state-owned shares and eventually implement full tradability. Heated discussions and debates on the ways to address the problem marked the “May 1999 - June 2001” bubble period until the crash in June 2001 following the historical high on 2001/06/13. Figure 11 shows an attempt to fit the (logarithm of the) SHSE Composite Index from January 1999 to July 2001, with expression (5) with $\tau = |t_c - t|$, in order to test whether we can detect a speculative bubble preceding the crash in July 2001. As can be seen, the fit does not qualify a clear LPPL signal because the exponent $m = 1$ is large and the oscillations are much more irregular than described by log-periodicity (5). According to the classification of Johansen and Sornette [64], the crash that followed this period should thus be characterized as “exogenous.” In fact, the crash was indeed directly triggered by the promulgation of the *Tentative Administrative Measures for Raising Social Security Funds through the Sale of State-Owned Shares* by the State Council of China⁷. On 2002/06/24, the State Council of China announced the removal with immediate effect of the provisions of the *Tentative Administrative Measures for Raising Social Security Funds through the Sale of State-Owned Shares*. The evolution of the SHSE Composite Index

⁷ According to the *Tentative Administrative Measures for Raising Social Security Funds through the Sale of State-Owned Shares*, a joint stock company in which the State holds an interest shall arrange for 10% of the existing State-owned shares to be sold as part of the offering, when conducting an initial or secondary offering to the public. The proceeds from the offering for sale will be contributed to national social security funds.

from May 1999 - June 2001 is probably due to a combination of speculative herding behavior and of policy-induced reactions, which is the probable cause of the absence of a clear-cut LPPL signal. This is one of those difficult cases where several processes intermix and blur the endogenous versus exogenous nature of the process. The state-owned share is still a dilemma for the Chinese policy-makers and the Chinese stock markets and is expected to continue to complicate the readings of the Chinese stock markets.

Steps in opening the stock markets to foreign investors are also very recent. The first foreign institutional investor bought in Chinese stock market no sooner than during the summer of 2003 (source: China Daily): UBS, one of the world's leading financial service firms, became the first foreign financial institution to invest in the US\$500 million A-share market in China. It placed its first order under the QFII (qualified financial institutional investor), which was previously open only to domestic investors. The long-anticipated deal, billed by many as a major boost to the market, failed to prop up China's flat yuan-currency A-share market. This step is just the beginning of an interesting development.

Our study shows that, notwithstanding all the idiosyncracies of the Chinese markets, universal LPPL signatures reflect the fundamental tendency of investors to speculate and herd.

6.3 Direction of capital flow: impact of a growing real estate bubble

The total amounts of Chinese household saving deposits were 64,332.4 billion yuan by the end of 2000, 73,762.4 billion yuan by 2001 and 86,910.65 billion yuan by 2002 and reached 108,000 billion yuan by the end of September 2003⁸. Over the long run, higher savings tend to increase domestic investment [66] but is also channelled in the stock market and in real estate. Indeed, there is not many alternative investments for individuals, the two main investment channels being the stock market and the real estate market.

Before the start of the 2001 antibubble, the increasing savings and the wealth effect [65] from market capitalization gains fed investments in real estate. After the crash and due to the continuing overall bearish nature of the Chinese stock market, there is less new capital attracted to the stock market. Available capital is thus finding other channels, the main one being in real estate. In addition, China's property market is boosted and is expected to continuously increasing in the coming decade after the successes of Beijing's bid for the 2008 Olympic Games, of Shanghai's bid for the 2010 World Expo, and of

⁸ Monthly historical data back to 1999 are available on the web site of the People's Bank of China at <http://www.pbc.gov.cn/english/baogaoyutongjishuju/>

China's entry to WTO. Although there are controversies on the existence of a real-estate bubble in China, it is accepted widely that regional bubbles exist. In Zhuji City (Zhejiang Province), which has a population of about 0.16 million people, the price of a 120 M² house almost doubled over one year from September 2002 to September 2003 from ¥165,000 RMB to about ¥300,000 RMB. In Xinzhuang of Shanghai, the house price in a same uptown roared from ¥2,800 /M² in November 2002 to ¥5,400/M² in October 2003. The Shanghai House Price Composite Index in October 2001 had a yearly growth of 27.8%. This growth rate is even a little bit higher than in London, where an unsustainable real-estate bubble may be in store [42].

Figure 12 shows the evolution of the Shanghai House Price Composite Index for different months⁹ with its fit to a pure power law (1). The inset shows the monthly growth rate. The fast increasing growth of the growth rate means that, not only the housing prices are growing fast, they are growing super-exponentially: not only is the growth rate large, it is growing and its growth is accelerating! These are the ingredients for the future development a finite-time singularity [68,14,69], announcing a tipping point and a strong change of regime, possible a crash. However, since the estimated critical time $t_c = 2008.80$ is far from the present time, this estimate is unreliable. It just implies that the house price will continue to roar at a high speed and probably increasing acceleration in the near future. We need to wait for more data to accumulate before a better timing of the end of this speculative bubble can be obtained. Further evidence of the existence of a speculative real-estate bubble is found in the load and mortgage reported by the People's Bank of China [67]. The super-exponential acceleration of real-estate prices reflected in the fast growth rate shown in Fig. 12 strongly suggests that a real-estate bubble is on its way in Shanghai and many other regions in China.

We should add that, in the recent two years, the Chinese real-estate market has been fuelled by foreign capitals as well. Foreign speculators's expectation of a *Renminbi* appreciation led an inflow of dozens of billions of US dollars (the "hot" money) in 2003. Part of the foreign capital are deposits in China's banks and the remaining is invested in China. If *Renminbi* appreciates, one can expect that the Chinese stock and property markets will further fuel a bull phase, as occurred in Japan in the second half of the 1980's. As the price skyrockets, the positive feedback provided by the increasing attraction of the real-estate market for foreigners will eventually result in an unsustainable bubble [14,15,43]. Our previous work has shown in several other contexts the strong positive feedbacks resulting from foreign capital fluxes (see [43] and references therein).

⁹ Monthly historical data back to August 2000 are available on the web site of Shanghai Real Estate Appraisers Association at <http://www.valuer.org.cn/scjg/>.

Fig. 12. Shanghai House Price Composite Index as a function of time and its fit to (1) with $I(t)$ being the logarithm of house price composite index. The parameters are respectively $t_c = 2008.80$, $m = -3.00$, $A = 6.42$, and $B = 74.1$. The inset gives the yearly growth rate.

7 Concluding remarks

In summary, we have identified an antibubble in the Chinese stock market which started in August 2001 after the crash in June 2001. The crash was probably the outcome of an instability maturing during the development of a bubble from May 1999 to June 2001 and was triggered by a significant policy announcement. It gave birth to the ensuing antibubble. This antibubble exhibits the hallmarks previously identified in other antibubble regimes in the last two decades, both in western and emergent markets. These signatures comprise a power law relaxation decorated with significant log-periodic undulations. The Chinese antibubble exhibits universal as well as idiosyncratic features when compared with other known stock market antibubbles. The antibubble in China's equity market may be linked to the rapid development of an ongoing property bubble in China, and vice-versa. The real-estate bubble that we have clearly identified is in turn fuelled by available capital from China's individual investors and commercial banks as well as increasing influx for foreign speculators. Our work shows that there is evident herding behaviors among stock traders in China in spite of the fact that the Chinese equity market is still immature and very much influence by government policy. Actually, we have found maybe even stronger imprints of herding that in other mature markets, probably due to the immaturity of the Chinese market which seems to attract short-term investors more interested in fast gains than in long-term investments.

Acknowledgments: We are grateful to Wen-Bin Mei who has kindly provided the historical data of all the 14 indexes and to Wei Deng for providing the Shanghai House Price Composite Index data. This work was supported by the James S. Mc Donnell Foundation 21st century scientist award/studying

complex system.
